I. SUMMARY

1

I. SUMMARY

The purpose of this study was to determine a suitable method(s) for estimating smoke intake in the human smoking population, both in an experimental setting and eventually in a survey-type situation. Although there have been studies in the past to determine smoke intake by analysis of various smoke components in body fluids, to our knowledge this is the first attempt to assemble in a single document much of the relevant knowledge available from the literature and other sources, including consultants.

Early in the study inquiries were made of various expert consultants for advice and suggestions relating to compounds or methods suitable for measuring smoke intake. It became clear that, although this approach was necessary for specific segments of the problem, it was inappropriate and inefficient for the ultimate objective since individual experts lacked essential information outside of their area of expertise. We have attempted to bring these various types of information together so that this report might provide scientists of diverse backgrounds with a broad perspective, which together with various clues and other facts may catalyze thinking about novel approaches to the measurement of smoke intake, in addition to those specifically proposed.

To this general end the report presents a compilation of:

- (1) Over 475 compounds reported in smoke, their amount and methods of analysis.
- (2) Over 20 compounds found in smoke which were previously reported in the literature to measure smoke intake, related information on the body fluid used, methods of analysis, and where stated or derivable, the reliability and limitations of the methodology.
- (3) Various biological responses, to whole smoke or to individual smoke components, which conceivably could be used as indicators of smoke intake.
- (4) The factors which influence the determination of smoke intake, e.g., level of smoke retention in body fluids, volume and availability of various body fluids, the degree of invasiveness needed for sampling, and pharmacokinetics of the marker compound once inhaled and absorbed.

- (5) Analytical procedures surveyed for the state-of-the-art, to optimize selection of appropriate methodology based on sensitivity, specificity and reproducibility. This effort has included not only commercially available instrumentation but also specialized research instrumentation used in a few research laboratories.

Our own analysis of the situation has led us to a recommendation that for the immediate future, two methodologies should be further developed for experimental studies. Since they involve the use of stable isotopes, in carbon monoxide and water, they might well not be suitable for survey studies but could provide a firm basis for calibration of survey methods with other compounds. Our reasoning leading to this recommendation is based on the following considerations.

- (1) A great many compounds are present in smoke in sufficient quantity to be useful as indicators for estimating smoke intake. In most instances, however, the amount of information available about the distribution, metabolism and elimination of these compounds was inadequate to permit an evaluation.
- (2) None of the biological responses examined appear to be sufficiently specific or attainable by ordinary sampling techniques to be considered prime candidates for determining smoke intake.
- (3) An in depth analysis of previous studies determined various sources of error and uncertainty. The major ones include: the inability of the investigator to control adequately the volume of smoke generated from each cigarette by the smoker; the inability to determine the fraction of generated smoke actually inhaled; the pharmacokinetics of the compound of interest, e.g., transfer rate from lung to body fluid; and finally, in many cases, changes in background levels of the marker compounds in body fluid, i.e., from endogenous and exogenous sources. These appear to be the major obstacles in any future studies on the development of methodology for estimating smoke intake quantitatively.
- (4) Compounds that have been reported in the literature as indicators of smoke intake include nicotine, cotinine (metabolite of nicotine), thiocyanate (cyanide metabolite), free cyanide, polonium 210, lead 210, thorium 228, bromine 82, cadmium, nitrogen, carbon monoxide, acetonitrile, and 1,2,3,4-dibenzo-pyrene. Although body tissue levels of many of the above compounds have been shown to be increased in smokers, the degree of correlation between smoking history and level of these compounds in a body fluid, with the exception of carbon monoxide

and acetonitrile, has not been impressive. Additional study is needed to confirm the high correlations found using acetonitrile.

Results of this study lead us to recommend further investigations of the potential applicability of carbon monoxide as an indicator of gas phase intake, particularly in the light of the extent of knowledge of its biochemical properties. Water, as a constituent of both particulate and gas phase of smoke, may also be useful as an indicator. However, in view of the presence in the body fluids of carbon monoxide and water from endogenous and exogenous sources other than cigarette smoke, it will be necessary to use a suitable method of tagging the compound in smoke. Use of the stable mass isotopes was selected since they provide a high degree of selectivity and instrumentation is available to maximize sensitivity.

The following subsidiary recommendations offer a logical development of this general recommendation, leading to methods for direct use in experimental situations, and providing a basis for development of survey methods.

- (1) To help differentiate the source of the marker compound in body fluid, i.e., to limit it to cigarette smoke versus other sources, a mass-isotope added to cigarette tobacco is recommended. Although many compounds are potentially good indicators of smoke intake, carbon monoxide and water are two which, if labeled with a mass-isotope (^{13}C , ^2D), show the most promise of offering this differentiation.
- (2) The use of ^{13}C carbon monoxide is recommended since it provides a non-invasive method and a measure of the amount of smoke (gas phase) actually inhaled. Also the level of tissue absorption and metabolism which complicate many quantitative studies of smoke intake is minimal. For analysis, our recommendation is the use of diode laser spectroscopy. This instrumentation provides a maximum in sensitivity and specificity. The suggested instrumentation is still a research tool and not available in most analytical laboratories, yet it is, in our best judgment, the most promising for providing methodology for determining smoke intake quantitation. The preparation of a compound containing ^{13}C or ^2D suitable for labeling tobacco which would produce labeled carbon monoxide or water, respectively, upon combustion should not involve major expenditure. We have considered several possible ways of labeling cigarettes, but the selection should not be considered final.

- (3) Cigarette smoking should be carried out with a calibrated smoking machine to control the amount of smoke generated and the level of the marker compound in mainstream smoke. In biological experiments, all smoke in exhaled breath (plus any which may be recovered from the mouth) should be collected to establish the amount not retained in the respiratory tract.
- (4) In a pilot study, smoke intake would be determined under standardized and well controlled exposure conditions using the tracheotomized dog initially, then a selected population of chronic smokers. Carbon monoxide would be the first compound to be evaluated.
- (5) Once a protocol for quantitatively estimating smoke intake using mass-isotope techniques is developed, other potential natural marker compounds can be calibrated for use in characterizing the intake of smoking populations involving large numbers of subjects.
- (6) Cigarette butts could be analyzed for different smoking modes to determine if there are differences in the build-up of various smoke components. These differences would serve as a crude measure of the degree of puffing versus smoldering of the cigarette.

Until such studies are actually carried out, an assessment of overall program cost is difficult to make. Analysis of trace gases by laser spectroscopy (as proposed in Section V and detailed in Section VI) for the detection of ^{13}C -carbon monoxide in expired air, will require a considerable initial capital outlay. The diode laser source assembly will cost approximately \$16,000 with additional components (which would be needed for any laser) costing another \$50,000. In terms of epidemiological studies of smoking, the cost of the proposed capital equipment would probably be small in relation to the total number of samples needed to characterize various segments of the smoking population.

II. INTRODUCTION

II. INTRODUCTION

The consequences of cigarette smoking on health have been reviewed in reports for the Surgeon General of the United States in 1964, 1968 and 1971. Based in large part on epidemiological studies, these reports conclude that there is a close statistical association between cigarette consumption and a variety of human diseases, notably lung cancer, chronic pulmonary disease and cardiovascular disease. A major problem in these epidemiological studies correlating cigarette smoking with systemic effects experienced by man, be they either irreversible disease states or transient impairment of physiological function, was a lack of quantitative assessment of actual smoke intake and retention.

For obvious reasons the rate of puffing, puff volume, depth of inhalation, time elapsed for smoke in the lung (time between smoke inhalation and exhalation), and many other factors -- all profoundly influence the overall retention of smoke components and are not accounted for in estimating dose or smoking history by inquiry or questionnaire.

Since smoke is composed of hundreds of different chemical compounds, reliable measurements of smoke intake are dependent on the proper selection of one (or more) component that is transferred from smoke to a physiological fluid (or, in the broader sense, body tissues) in a very reproducible manner during smoking. Moreover, the fate of a suitable compound must be well understood in terms of its distribution, metabolism and excretion, as well as those factors that would tend to influence its stability in the smoke. Finally, the practical aspects of body fluid analysis, e.g., sensitivity, specificity, cost of analysis, and a use of non-invasive methodology to acquire tissue fluids, have helped shape the conclusions of this report.

To clarify the problems of quantitating smoke intake in human subjects, selected experts in related fields have been consulted and have provided considerable direction, especially in areas of analytical instrumentation. A literature search was used to define relevant knowledge from past research.

III. LITERATURE SURVEY

III. LITERATURE SURVEY

A. SOURCES

Due to the extensive literature related to the biology and chemistry of cigarette smoke, in part our efforts have been directed toward compilation of a list of those chemical compounds which occur in smoke in sufficient quantities so that they would be present in measurable levels in body fluids using existing published methodology. To accomplish this it was necessary to compile from the published literature a list of chemical compounds reported in cigarette smoke, the amount, and the methods of analysis.

In addition to an extensive compilation of literature in the ADL files the following sources were also searched: Chemical Abstracts (1/1960-6/1974); Biological Abstracts (1/1967-6/1973); Index Medicus (1/1960-6/1973); the Reports of the Surgeon General on the Health Consequences of Smoking (1964, 1968, 1971); and The Bibliography on Smoking and Health, National Clearinghouse for Smoking and Health, HEW (1/1968-6/1973). We have consulted with the editor of The Bibliography on Smoking and Health and with the Assistant Director for Information Services of NERAC computerized data service at the University of Connecticut, Storrs, Connecticut. A computerized literature search was also carried out through the National Library of Medicine in both the MEDLINE and the MEDLARS programs, and also the Preston Technical Abstract Service.

The MEDLINE search (1970-3/1974) produced 578 citations under the following key words: *complications of smoking* (276 citations); *carbon monoxide/blood or carbon monoxide/urine or carbon monoxide/analysis* (251 citations); *carbon monoxide and breath tests* (no citations); *carbon monoxide and blood gas analysis* (13 citations); *nicotine/blood* (11 citations); *dose-response relationship, smoke* (14 citations); and *smoking/pathology* (13 citations).

The MEDLARS search (1/1964-5/1973) furnished 873 citations under the following key words: *smoking and blood, smoking and urine, smoking and lymph, smoking and hemolymph, smoking and plasma* (693 citations); *smoking and other body fluids* (180 citations).

The Preston Technical Abstract Search (1960-1971) produced 84 citations (key word: *cigarette smoke*).

Certain operational problems associated with the literature search soon became apparent, particularly with respect to the computerized aspects of the literature search. All of the computerized data retrieval systems were categorized and classified under certain key words. Due to the enormous volume of smoke related papers in the literature, plus the broad scope of our inquiry which overlapped into several areas, the available key words were not specific enough for our purposes. Since we could not coordinate the key words programmed into the computer with

our particular needs, we requested, by necessity, several key words to ensure receiving all citations relevant to smoke intake analysis. This action resulted in many citations unrelated to our specific aims. For example, citations under smoking and health might include papers concerned with various disease states which coincidentally made mention of the smoking history of the individual(s), or perhaps papers concerned with the effects of marijuana smoking, etc.

To deal effectively with all the published literature, it was necessary to have many foreign publications translated into English.

To assist the reader, a list of frequently used abbreviations for the method of analysis is included.

LIST OF ABBREVIATIONS FREQUENTLY
USED IN REFERRING TO METHODS OF ANALYSIS

GC	Gas Chromatography
GCFPD	Gas Chromatography with Flame Photometric Detector
GCFID	Gas Chromatography with Flame Ionization Detector

B. COMPOUNDS IN SMOKE REPORTED IN BIOLOGICAL FLUIDS

The bulk of previous studies to estimate smoke intake has focused on measuring nicotine, thiocyanate, or carbon monoxide in either blood, urine, saliva or expired air. Here we would like to focus on some of the complications in published procedures.

Various methods have been used to determine the concentration of nicotine in an individual who smokes and these studies have shown that nicotine is rapidly metabolized and the molecule is rather unstable in neutral and alkaline solutions, undergoing a variety of chemical changes. These factors have probably contributed to the great variability in the results of nicotine, and its metabolite cotinine, determination in urine. This has been demonstrated by Becket³⁸, who artificially maintained the urine at an acidic pH by the administration of ammonium chloride tablets to the test subjects. Another metabolite, nicotine-1'-oxide is independent of urinary pH but the amount present is small (Beckett³⁸).

Urinary nicotine analysis often requires a 24-hour sample and tedious extraction and assay procedures (Beckett^{38,39}), (Bowman⁶³) (Booth⁶⁰) (Dagne¹²⁴). Moreover, sex dependent changes in excretion (Becket³⁹) must also be taken into account; and smoking is believed to induce enzymes that alter the metabolism of nicotine (Beckett⁴¹). When both smokers and non-smokers were administered intravenously identical doses of nicotine, smokers excreted lower levels of nicotine, although levels of cotinine were comparable in both groups. This finding would lead one to question the use of urinary nicotine as a measure of smoke intake. Blood nicotine analyses, in general, provide more reliable data on body burden than do analyses of urinary nicotine excretion (Schievelbein⁴⁷⁴) (Isaac²³⁷).

Nicotine is rapidly eliminated from the bloodstream e.g., 30 seconds (Isaac²³⁶)], and within a few minutes the concentration drops below the levels of gas chromatographic detectability (Isaac²³⁶) (Schievelbein⁴⁷⁴). Also, the rate of plasma decline shows a considerable degree of variability between smokers (Isaac²³⁷). Langone, Gjika and Van Vunakis²⁸⁶ have recently developed a highly sensitive radioimmunoassay procedure for detecting nicotine and/or cotinine either in blood or urine. However, they report no apparent correlation between the number of cigarettes smoked and the concentrations of nicotine and cotinine in body fluids when using their procedure, although within each subject there is a well defined decrease in concentration with time after smoking.

A list of compounds found in smoke which have been isolated from one or more of the body fluids is presented in Table 1. Other compounds in addition to nicotine, carbon monoxide and thiocyanate reported in body fluids include polonium-210, lead (also 210), thorium-228, cadmium, nitrogen, methanol, furfural, acetonitrile, 3,4-benzpyrene, and bis(p-chlorophenyl) acetic acid.

ABBREVIATIONS USED IN TABLE 1

↑	Increases, higher
↓	Decreases, lower
→	Leads to, causes
COHb	Carboxyhemoglobin
BUN	Blood urea nitrogen
SGOT	Serum glutamic oxalic transaminase
SGPT	Serum glutamic pyruvic transaminase
LDH	Lactic dehydrogenase
HR	Heart rate
BP	Blood pressure
NEFA	Non-esterified fatty acid
FFA	Free fatty acid
FA	Fatty acid
5-HT	5-Hydroxytryptamine
NE	Norepinephrine
EPI	Epinephrine
5-HIAA	5-Hydroxy-3-indole acetic acid
ADP	Adenosine diphosphate

<u>Component</u>	<u>Reference</u>	<u>Method of Analysis</u>	<u>Presence in Tissue or Fluid</u>	<u>Concentration/Findings</u>
CO (Smoke)	Landaw (283)	IR (Expired air)	Expired air, Blood (Man)	(a) A linear correlation ($r = .93$) was found between CO concentration in expired air and COHb in a simultaneous venous sample of blood.
		GC (COHb)		(b) There was great variability among smokers having similar smoking habits.
CO (Smoke)	Ringold (448)	IR	Expired air, Blood (Man)	(a) Relationship between expired air CO and COHb is: $\text{COHb\%} = 0.5 + \frac{\text{CO (ppm)}}{5}$
				(b) Higher COHb levels were found in cigarette smokers than non-smokers or smokers of pipes or cigars.

TABLE 1 (cont.)

AGENTS IN CIGARETTE SMOKE FOUND IN BIOLOGICAL FLUIDS FOR ASSESSMENT OF SMOKE INTAKE

<u>Component</u>	<u>Reference</u>	<u>Method of Analysis</u>	<u>Presence in Tissue or Fluid</u>	<u>Concentration/Findings</u>	
CO (Smoke)	Stewart (511)	GCFID	Expired air (Man)	(a) Smokers N=1620	%COHb 4.47±0.06 (SE)
		CO-oximeter	Blood (Man)	Non-smokers N=2798	%COHb 1.33±0.02 (SE)
				(b) Equation relating %COHb and CO ppm in expired air is: %COHb = 0.25 (CO ppm) + 0.48	
				(c) Good relationship between CO levels and smoking habits up to 1.5 packs/ day. Above this point there is no further appreciable increase in CO levels.	
CO	Yacoub (574)	C	Blood (Man)	(a) Smokers (20 cigs/day) who did not inhale had + CO blood levels (12.1 ml) when compared to inhalers (18.8 ml/liter blood).	
				(b) Both groups were > non-smokers (3.05 ml CO/liter).	
				(c) Concomitant Δ in urinary SCN was seen: Non-inhalers 16.3 mg/L Inhalers 19.4 mg/L Non-smokers 4.5 mg/L

Arthur D Little Inc

The published literature is in agreement that thiocyanate levels in either saliva, blood, or urine of smokers are higher than the levels found in non-smokers. Numerous investigators have reported an increase in plasma thiocyanate levels (SCN^-) in smokers, Foulds,¹⁶⁵ Bhowm,⁴⁸ Pettigrew,^{415,416} Dastur,¹²⁹ Densen,¹³⁵ Bourke,⁶¹ Beck,³⁷ and Wilson.⁵⁷⁰ Eliakis¹⁴⁸ states that serum SCN^- levels increase as a function of the number of cigarettes smoked per day. A similar relationship has been reported for urinary SCN^- levels (Yacoub⁵⁷⁵) while most reports simply show a higher level of urinary SCN^- in smokers, Linnell,³⁰⁶ Maehly,³¹⁵ Densen,¹³⁵ Barylko-Pikielna,³³ and Djuric.¹⁴¹ Likewise, salivary SCN^- levels are higher in smokers, Langmann,²⁸⁵ Densen,¹³⁵ Dogen,¹⁴³ Courant,¹¹⁶ Barylko-Pikielna,³³ Dacre,¹²³ Cruz Urbina,¹²¹ and Wray,⁵⁷¹ but wide daily variations in the level of SCN^- in saliva have been reported (Dacre¹²³).

Determination of SCN^- in body fluids is uncomplicated, rapid and inexpensive, and it would be ideal if these levels were a reliable index of smoke intake. Moreover, Pettigrew⁴¹⁵ reports that plasma SCN^- levels gradually drop to non-smoking levels within four weeks after the cessation of smoking. This would seem to indicate that the higher levels seen in smokers are directly associated with smoking. However, although SCN^- levels are elevated and roughly proportional to the level of smoking, subject variability precludes usage of SCN^- concentrations as a reliable index of individual smoking consumption. Densen¹³⁵ also reported wide variations among individuals and concludes that these variations may indicate metabolic adjustments to years of tobacco exposure. Djuric¹⁴¹ has found considerable individual differences in urinary levels of thiocyanate and these variations may reflect dietary intake since many foods, e.g., almonds, cabbage, garlic, mustard, radishes, etc., give rise to thiocyanate in body tissues and could mask the effects of smoking.

The influence of body cyanide may introduce additional complications in SCN^- determination because blood samples are not suitable for the detection of low cyanide concentrations due to the high rate of metabolism by the enzymatic Rhodanese or 8-mercaptopyruvate trans-sulfurase. Thus, this may account for the discrepancy of Maehly³¹⁵ who reported a higher cyanide level in the blood of smokers, whereas Pettigrew⁴¹⁶ has observed no difference in whole blood cyanide concentrations.

Therefore, despite the fact that smokers have higher thiocyanate levels in body fluids, the large degree of variability within and between individuals makes measurement of thiocyanate concentrations unsuitable as a reliable measure of smoke intake.

The determination of carbon monoxide (CO) in body tissues and expired air has been pursued by numerous investigators, and despite many variables (e.g., occupation, sex, health status, or environment) which might obscure the results, it can be concluded that chronic smokers have higher carboxy-hemoglobin (COHb) levels than non-smokers. Employing spectrophotometric methods of analysis, Bowden,⁶² Yacoub,⁵⁷⁴ and Jones²⁴⁸ have reported five

percent and higher COHb levels in smokers. These methods measure blood CO levels indirectly by measuring COHb saturation.

Landaw²⁸³ reduced CO to CH₄ in a H₂ stream at 300°C over a metallic surface. The CH₄ was then detected with gas chromatography using a flame ionization detector. He found a linear correlation between CO levels in expired breath and blood. Landaw further reported great individual variability despite very similar smoking habits.

Anderhub⁷ and Stewart⁵¹¹ used a CO-oximeter to measure COHb. The instrument is rapid and precise but has one major disadvantage in that it must be calibrated daily against a known standard of human blood which must be determined by gas chromatographic or other instrumentation.

Cohen,¹⁰⁷ Ringold,⁴⁴⁸ and Stewart⁵¹¹ measured CO in expired air. The advantages of this method include the ease of sampling, its rapidity, and the non-invasive aspect of sampling. On the other hand, this method necessitates a sampling device which is impermeable to CO and capable of retaining gas samples without change in composition. Broad variations could also result due to collection techniques.

Stewart⁵¹¹ has reported a good relationship between CO levels and smoking habits up to 1.5 packs per day. Beyond this point he reports no further appreciable increase in CO levels. Based on these findings the CO levels could be used to measure the degree of smoke for intake among light smokers, but would not permit discrimination of smoke intake on a daily basis beyond the 1.5 pack level.

Other agents have been measured in an attempt to quantitate the dose of smoke an individual actually receives. These agents include lead, cadmium, acetonitrile, some polycyclic hydrocarbons, and the radioactive elements polonium-210, lead-210, thorium-228 and bromine-82.

Jones²⁴⁸ found no significant statistical difference in blood lead levels of smokers when compared with non-smokers. This confirms identical results published by Lehnert²⁹⁷ using atomic absorption spectroscopy. Lewis³⁰³ reported finding higher mean composite levels of cadmium per organ in the liver, kidney, and lungs at necropsy in humans who smoked. Although smokers do accumulate cadmium with cigarette-pack-years, tissue biopsy is far too drastic a procedure to use for quantitating smoke intake. Additionally, certain foods contain measurable amounts of cadmium (e.g., fish, wheat, oats, and many dairy products) which could influence the results.

Dalham¹²⁶ measured the percent retention in humans of acetonitrile present in smoke using gas chromatographic analyses of expired breath. He found a total of 74% retention in the mouth and a 91% retention in mouth and lungs. McKee³²⁸ has reported a definite correlation ($r = .707$) between smoking and the concentration of acetonitrile in the urine. This is a surprisingly high correlation. No mention was made of the cigarette brand, filtered or non-filtered. Smoke intake was based on the smoker's subjective evaluation. This finding should be evaluated more fully.

Some polycyclic hydrocarbons, most notably 3,4-benzpyrene, have been found in human urine, sputum, and in lung biopsy tissue. Vassar,⁵³⁶ using fluorescence microscopy, reports a direct positive relationship between the number of cigarettes smoked and the number of fluorescent macrophages in the lung; this finding is believed to be a result of polycyclic hydrocarbons being taken up by the histiocytes. A significant increase in the activity of aryl hydrocarbon hydroxylase has been seen in the placentas of smoking mothers (Pelkonen⁴¹⁰). However, Mallet³¹⁷ found 3,4-benzpyrene at necropsy in the urine of a smoker, but found even higher levels in a child raised in the polluted atmosphere of a large city. This entire area concerning the relationship of fluorescent macrophages and enzyme inducibility with exposure to polycyclic hydrocarbons has too many variables to be indicative of smoke intake since benzpyrene is found in car exhausts, in certain foods, etc.

Recently attempts have been made to detect in smokers radioisotopes which occur naturally in tobacco smoke. Petushkov,⁴¹⁸ working with thorium-228, tried to clarify the peculiarity of distribution and the rapidity of removal of thorium-228 and its decomposition products after it is transferred from smoke to humans. The radionuclides, polonium-210 and lead-210, have been found in higher levels in body fluids of smokers vs. non-smokers (Bogner⁵⁸) (Little,^{307,308}) and are a direct result of increased absorption of these radioisotopes from cigarette smoke. Wehner⁵⁵³ has gone one step further and by means of neutron activation, labeled cigarettes with bromine-82 and measured the amount of gamma radiation present in dog's blood after smoking these cigarettes. Although this method is relatively easy in both procedure and analysis, it exposes the test subject to radiation.

C. COMPOSITION OF CIGARETTE SMOKE AND METHODS OF ANALYSIS

Individual chemical components of smoke that have been reported in the literature are tabulated in the following pages. An attempt has been made to group individual compounds according to the chemical classifications used by previous workers. Data on the amount in smoke, if available, are also provided for each compound. All data are expressed in $\mu\text{g}/\text{cigarette}$. It was necessary to assume cigarettes contained one gram of tobacco, the volume of a puff is 35 ml, and 8 puffs can be taken from one cigarette. Frequently different amounts were reported by different workers. For these compounds the range of values is provided.

The major objective of this report was to select a main stream cigarette component that when quantitated in body tissues would serve as a measure of smoke intake. Selection of an appropriate marker compound can be attempted, however, only if its concentration in the appropriate body fluid is known along with some understanding of its detectability. In view of the limited information on tissue distribution of individual chemical compounds in smoke, it was impossible to evaluate a priori a suitable marker compound. To overcome this limitation we have taken the concentration of the compound reported in smoke along with its analytical detectability and calculated the sample size of body fluid needed to measure the marker after smoking one cigarette. This required an assumption that each compound distributed itself uniformly throughout soft tissues (body mass less bone).

The sample size needed to provide sufficient concentration for analysis of the marker in body fluid is calculated by dividing the sensitivity of the method by the quantity found in one gram of tissue (tissue fluid). The method of analysis for each compound and the name of the investigators are listed on the table immediately following one containing the estimated sample sizes.

Abbreviations Used for Compounds Reported in Smoke

- t = Trace amount.
- Q = Smoke component was identified, but not quantitated.
- a = Original published data reported as per puff. To obtain values per cigarette, all values were multiplied by eight.
- b = Original published data based on grams of tobacco smoked. The values in this table were calculated on the basis of a one-gram cigarette.
- c = Original published data reported as amount per liter of smoke. The values in this table were calculated on the basis of a 280-ml (35 x 8) volume of smoke from one cigarette.
- d = Original published data reported as vol. %. Calculations were based on a 280-ml volume of smoke.
- e = Original published data reported as mole %. Values in this table were converted to $\mu\text{g}/\text{cigarette}$ on the basis of a 280-ml volume of smoke.
- f = Original published data reported as ppm. Values in this table were converted to $\mu\text{g}/\text{cigarette}$ on the basis of a 280-ml volume of smoke.
